Manganese-Induced Parkinsonism Associated With Methcathinone (Ephedrone) Abuse

Rob M. A. de Bie, MD, PhD; Richard M. Gladstone, MD; Antonio P. Strafella, MD, PhD; Ji-Hyun Ko, MSc; Anthony E. Lang, MD

Background: Manganese intoxication may lead to a levodopa-resistant, akinetic-rigid syndrome. A new form of presumed manganese poisoning has been reported in drug-addicted persons from Russia, Ukraine, and Estonia who have intravenously injected self-prepared methcathinone hydrochloride (Ephedrone).

Patient: A 36-year-old man from Azerbaijan with hepatitis C and only modest hepatic synthetic dysfunction developed rapid-onset, levodopa-resistant parkinsonism with profound hypophonia.

Manganese intoxication may lead to a levodopa-resistant, akinetic-rigid syndrome with particular signs of pronounced dysarthria and impaired posture reflexes. In affected patients, T1-weighted magnetic resonance images of the brain can show symmetric hyperintense signals in the basal ganglia, especially the globus pallidus and region of the substantia nigra in the midbrain. A new form of presumed manganese poisoning has been reported in drug-addicted persons from Russia, Ukraine, and Estonia who have intravenously injected self-prepared methcathinone hydrochloride (Ephedrone), which is synthesized from pseudoephedrine hydrochloride using potassium permanganate as a potent oxidant. Neurologists outside of eastern bloc countries should be aware of this consequence of drug abuse.

In April 2005, a right-handed, 36-year-old man from Azerbaijan noticed a decrease in libido. Shortly thereafter, he experienced excessive sleepiness and slowness of movements. The symptoms were rapidly progressive in the first few months and seemed to stabilize thereafter. He was difficult to understand because of his soft speech and palilalia. He had no drooling but choked occasionally. Walking was difficult, though he did not report balance problems. He experienced jerky movements of his legs during the night. His handwriting became slower, smaller, and difficult to read. Fine motor movements including buttoning and using cutlery were impaired. Except for nocturia twice a night, he reported no urinary problems. He had no gastrointestinal tract symptoms.

In 2004, the patient had started to intravenously inject himself once or twice daily with a methcathinone solution prepared by combining 12 tablets containing 60 mg of pseudoephedrine hydrochloride (Sudafed; Pfizer Canada Inc, Markham, Ontario) with 0.3 g of potassium permanganate. When first seen, he did not admit this drug abuse to his physicians.

His medical history included hepatitis C virus infection acquired while self-injecting methcathinone in Russia in the early 1990s. He received interferon alfa monotherapy in Israel in 1998.

At physical examination, the patient was alert and well oriented. He had a pro-
nounced masked facies and extreme hypophonia resulting in his speech being largely unintelligible. Cognitive assessment was limited by communication difficulties; the components of the Montreal Cognitive Assessment (MoCA) that could be tested revealed no overt deficits. He had some slowing and mild restriction in the range of vertical saccadic eye movements, horizontal saccades were somewhat slowed, and vertical optokinetic nystagmus was impaired. There was moderate bilateral limb bradykinesia. Tone in the limbs was normal, but there was mild axial rigidity. He walked with short strides with a slightly wide base, and his arms were held abducted from the sides. Turning was difficult and postural reflexes were impaired, with falling on the pull test. Neurologic examination findings revealed no other abnormalities. Findings at general examination were unremarkable. The patient had one spider nevus on his chest and injection stigmata, particularly on the left arm, although when asked about these at the initial examination, his wife immediately indicated that they were the consequence of a previous operation.

Pramipexole dihydrochloride at doses of up to 0.75 mg/d had no effect on the parkinsonism but eliminated the jerky movements of his legs at night. This drug therapy was discontinued because of excessive daytime sleepiness and its stimulating a craving for sweets. Trials of sele-giline hydrochloride and levodopa-carbidopa at doses up to 600/150 mg/d were ineffective.

Magnetic resonance images of the brain showed striking symmetric increased signal in the globus pallidus, substantia nigra, dentate nucleus, and pontine tegmentum on T1-weighted images (Figure) with little correlation on T2-weighted images (not shown), which demonstrated only modest hyperintensity in the region of the posterior limb of the internal capsule. There was no evidence of edema. Laboratory tests showed normal concentrations of blood albumin, alkaline phosphatase, γ-glutamyl transferase, total bilirubin, ceruloplasmin, serum copper, and 24-hour urine copper. Prothrombin time was 51.8 seconds (reference range, 33-43 seconds); aspartate aminotransferase level, 67 U/L (reference range, 10-40 U/L); and alanine aminotransferase level, 114 U/L (reference range, 2-60 U/L). Blood manganese concentration was 49 µg/L (897 nmol/L) (reference range, 4-16 µg/L [78-289 nmol/L]), and urine manganese concentration, 2804.3 nmol/24 h. A second blood manganese concentration 5 months after the first determination was 102 µg/L (1860 nmol/L) while the patient was still self-injecting methcathinone but before he admitted this to us. Tests for hepatitis A and B yielded negative results. Hepatitis C RNA was 405 000 IU/L, and a percutaneous liver biopsy specimen showed chronic active hepatitis with fibrosis. 6-[18F]-Fluorodopa positron emission tomography performed as previously described showed a mild reduction in fluorodopa uptake (Ki) limited to the posterior putamen (Table).

Although during the course of investigations we informed the patient that we believed his symptoms were caused by elevated manganese levels, he did not inform us of his drug abuse. He continued the injections of methcathinone until his wife revealed this several months later. Referral to a rehabilitation clinic was declined. After the initial discovery of elevated manganese levels, the patient underwent treatment by a naturopathic physician that included 10 sessions during 4 months using intravenous calcium disodium–EDTA at a dose of 3 g per treatment. This had no appreciable effect on his symptoms.

The designer drug methcathinone is also known as Cat, Jeff, Mulka, and Ephedrone. It was used as an antide-
pressant in the former Soviet Union and is very addictive. Methcathinone can be produced from pseudoephedrine (Sudafed) with potassium permanganate added to produce an oxidant reaction. Cases of ephedronic encephalopathy have been reported from Russia, Ukraine, and Estonia. To our knowledge, this is the first case occurring outside this region. Global travel and easy access to the Internet, where the recipe for the synthesis of methcathinone is readily available, make it possible that this disorder will become a more widespread public health problem.

Patients manifest clinical features typical of other causes of manganese, most notably a levodopa-resistant form of parkinsonism, particularly with myoclonus, speech dysfunction, postural instability and gait disorder (including the “cock walk”), hypersomnolence, and bradyphrenia. Our patient also demonstrated oculomotor dysfunction, in particular, vertical gaze slowing and limitation that have been noted in other disorders in which the globus pallidus is predominantly affected. Magnetic resonance images typically demonstrate the hyperintensities seen on T1-weighted images in our patient. To date, the prognosis of the syndrome is uncertain. Some patients have had mild to modest improvement during long-term follow-up, either spontaneously or after chelation therapy with EDTA. In contrast, as well described in patients with prolonged exposure to high levels of manganese in the workplace (eg, manganese ore miners and alloy plant workers), some have experienced clear progression of neurologic symptoms with time despite cessation of the exposure.

The role of hepatic dysfunction in causing this patient’s neurologic disorder is unclear. Cirrhosis is well known to be associated with increased signal intensity in the basal ganglia on T1-weighted images, presumably related to elevated blood manganese levels, and this is a proposed mechanism for the pathogenesis of acquired hepatolenticular degeneration. Recently, Schaumburg et al described a highly exposed worker who developed symptoms and signs of early manganese only after the onset of moderate hepatic dysfunction caused by hepatitis C infection. This case illustrates that even asymptomatic hepatic disease can be a risk factor in persons with substantial exposure to manganese. However, the route and quantity of exposure differ considerably between our patient and this case; our patient had relatively intact hepatic synthetic function, and hepatic dysfunction does not seem to have been a predisposing factor in other patients with ephedronic encephalopathy. Our patient abused intravenous methcathinone apparently prepared in the same manner in the early 1990s without neurologic consequences, presumably before development of his current level of hepatitis C–related hepatic dysfunction. The number of persons who have repeatedly abused methcathinone far exceeds the number with this neurologic syndrome. The underlying factors that contribute to the eventual development of this disorder, including variability in the preparation of the drug and the amount of manganese remaining in the solution, the presence of other contaminants, the potential direct toxic effect of methcathinone, or the presence of predisposing systemic illnesses such as hepatic dysfunction, remain to be evaluated.

Announcement

Trial Registration Required. In concert with the International Committee of Medical Journal Editors (ICMJE), Archives of Neurology will require, as a condition of consideration for publication, registration of all trials in a public trials registry (such as http://ClinicalTrials.gov). Trials must be registered at or before the onset of patient enrollment. This policy applies to any clinical trial starting enrollment after July 1, 2005. For trials that began enrollment before this date, registration will be required by September 13, 2005, before considering the trial for publication. The trial registration number should be supplied at the time of submission.

For details about this new policy, and for information on how the ICMJE defines a clinical trial, see the editorial by DeAngelis et al in the January issue of Archives of Dermatology (2005;141:76-77). Also see the Instructions to Authors on our Web site: www.archneurol.com.
