Isolated Mitochondrial Myopathy Associated With Muscle Coenzyme Q<sub>10</sub> Deficiency

Seema R. Lalani, MD; Georgirene D. Vladutiu, PhD; Katie Plunkett, MS; Timothy E. Lotze, MD; Adekunle M. Adesina, MD, PhD; Fernando Scaglia, MD

**Background:** Primary coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>) deficiency is rare. The encephalomyopathic form, described in few families, is characterized by exercise intolerance, recurrent myoglobinuria, developmental delay, ataxia, and seizures.

**Objective:** To report a rare manifestation of CoQ<sub>10</sub> deficiency with isolated mitochondrial myopathy without central nervous system involvement.

**Methods:** The patient was evaluated for progressive muscle weakness. Comprehensive clinical evaluation and muscle biopsy were performed for histopathologic analysis and mitochondrial DNA and respiratory chain enzyme studies. The patient began taking 150 mg/d of a CoQ<sub>10</sub> supplement.

**Results:** The elevated creatine kinase and lactate levels with abnormal urine organic acid and acylcarnitine profiles in this patient suggested a mitochondrial disorder. Skeletal muscle histochemical evaluation revealed ragged red fibers, and respiratory chain enzyme analyses showed partial reductions in complex I, I + III, and II + III activities with greater than 200% of normal citrate synthase activity. The CoQ<sub>10</sub> concentration in skeletal muscle was 46% of the normal reference mean. The in vitro addition of 50 µmol/L of coenzyme Q<sub>10</sub> to the succinate cytochrome-c reductase assay of the patient's skeletal muscle whole homogenate increased the succinate cytochrome-c reductase activity 8-fold compared with 2.8-fold in the normal control homogenates. Follow-up of the patient in 6 months demonstrated significant clinical improvement with normalization of creatine kinase and lactate levels.

**Conclusions:** The absence of central nervous system involvement and recurrent myoglobinuria expands the clinical phenotype of this treatable mitochondrial disorder. The complete recovery of myopathy with exogenous CoQ<sub>10</sub> supplementation observed in this patient highlights the importance of early identification and treatment of this genetic disorder.

_Arch Neurol._ 2005;62:317-320
He lost weight over this interval and complained of lower extremity muscle cramps. There was no history of unexplained fever, rash, ataxia, hearing loss, or seizures. Family history was unremarkable for neuromuscular disorders. On physical examination he was noted to have significantly reduced proximal muscle strength at the shoulders and the hips, with mild wasting of the shoulder muscles. The Gower maneuver was noted when arising from a seated position. There was no evidence of ophthalmoplegia or ataxia. His creatine kinase level was elevated at 359 U/L (reference range, 55-215 U/L), his lactate level was 33.33 mg/dL (3.7 mmol/L) (reference range, 1.80-18.01 mg/dL [0.2-2.0 mmol/L]), and his urinalysis demonstrated normal cardiac function. The patient was treated with 150 mg/d of a CoQ10 supplement and 100 mg/kg per day of carnitine for 3 months. On a 3-month follow-up visit, a remarkable improvement in muscle strength and absent Gower sign. Based on his considerable improvement with antioxidant therapy, the CoQ10 concentration was analyzed by high-performance liquid chromatography in the original skeletal muscle specimen and found to be 46% of the normal reference mean. The in vitro addition of 50 µmol/L of coenzyme Q10 to skeletal muscle histochemical evaluation revealed rare pale-staining myofibers with the cytochrome-c oxidase stain and scattered ragged red fibers with the Gomori trichrome stain (Figure). On electron microscopy, there was an increase in the number of mitochondria, although no abnormally shaped or enlarged mitochondria were found. A prominent increase in lipid droplets and subsarcolemmal and intermyofibrillar accumulation of free glycogen were found. In muscle, total and free carnitine values were 2.3 SDs below the normal reference mean. Fatty acid-oxidation enzymes and carnitine palmitoyltransferase activities in muscle were normal. Common mitochondrial DNA point mutations and deletions were not detected in skeletal muscle or lymphocytes. The RC enzyme analyses showed partial reductions in complex I, I + III, and II + III activities (Table) with greater than 200% of normal citrate synthase activity, suggestive of increased mitochondrial content and corroborating histochemical findings. Results of magnetic resonance imaging and magnetic resonance spectroscopy of the brain were normal. An echocardiogram demonstrated normal cardiac function. The patient was treated with 150 mg/d of a CoQ10 supplement and 100 mg/kg per day of carnitine for 3 months. On a 3-month follow-up visit, a remarkable improvement in muscle strength was noted with increased proximal muscle strength and absent Gower sign. Based on his considerable improvement with antioxidant therapy, the CoQ10 concentration was analyzed by high-performance liquid chromatography in the original skeletal muscle specimen and found to be 46% of the normal reference mean. The in vitro addition of 50 µmol/L of coenzyme Q10 to

the succinate cytochrome-c reductase assay of the patient's skeletal muscle whole homogenate increased the succinate cytochrome-c reductase activity 8-fold compared with a 2.8-fold increase in the normal control homogenates. Citrate synthase activity was not influenced by the addition of coenzyme Q1 to the assay in patients or in controls (data not shown). The CoQ10 supplementation was increased to 300 mg/d at the 3-month visit and within 6 months of therapy, both the creatine kinase (140 U/L) and lactate (5.4 mg/dL [0.6 mmol/L]) levels normalized, with sustained clinical improvement.

**COMMENT**

Our findings in this case study suggest that CoQ10 deficiency and the concomitant significant reductions in complex I, I + III, and II + III enzymatic activities in the RC were responsible for the mitochondrial disorder observed in our patient. The observed muscle carnitine deficiency is most likely related to an increased reduced nicotinamide adenine dinucleotide–nicotinamide adenine dinucleotide–coenzyme A ratio associated with respiratory chain defects.13 The increased ratio could impair β-oxidation at the level of 3-hydroxacyl-coenzyme A dehydrogenases, with a subsequent accumulation of acyl-coenzyme A β-oxidation intermediates. These intermediates, released as carnitine esters, are transported into plasma and eliminated in urine, leading to secondary carnitine deficiency.16,17

A recent study of 13 patients with childhood-onset cerebellar ataxia and marked CoQ10 deficiency suggested a cutoff for primary CoQ10 deficiency in muscle at 55% of the normal reference mean.18 Our patient's muscle CoQ10 activity was 46% of the normal reference mean. This result, in conjunction with the in vitro augmentation of residual muscle complex II + III activity with the addition of exogenous coenzyme Q1 to the assay and the successful clinical outcome with CoQ10 therapy, suggests primary CoQ10 deficiency in our patient. However, the molecular elucidation of this disorder will be required to confirm a primary defect in the ubiquinone biosynthetic pathway in all of these cases. We could hypothesize that the partial deficiency of CoQ10 observed in our proband perhaps accounts for the late clinical manifestation and isolated muscle involvement. However, detailed review of the reported cases indicates no clear correlation between the observed in vitro muscle or fibroblast CoQ10 levels and the severity in phenotype and/or age of onset in the affected individuals. This is illustrated by the presence of undetectable CoQ10 levels in fibroblasts in 2 siblings, one with widespread multisystem involvement and the other with a milder form of the disease.7 In another report of childhood-onset cerebellar ataxia and marked CoQ10 deficiency,18 patients who exhibited muscle CoQ10 concentrations of 2.9 µg/g and 14.8 µg/g, respectively, had a similar phenotype of ataxia and cerebellar atrophy by 9 years of age with no developmental delay or seizures.

Coenzyme Q10 plays an important role in the mitochondrial RC by acting as a redox carrier, transferring reducing equivalents from complex I and complex II to complex III.19 Coenzyme Q10 allows the extrusion of protons from the matrix to the intermembrane space along with the electron flow through the RC.20 Deficiency of CoQ10 impairs the proton transfer across the inner mitochondrial membrane, thus affecting generation of adenosine triphosphate and all adenosine triphosphate–dependent metabolic processes. Although the antioxidant treatment for RC defects has no proven efficacy, treatment of ubiquinone deficiency might represent an exception. A defective incorporation of tritium (H)–mevalonate into CoQ10 in fibroblasts initially suggested a specific site of impairment of endogenous CoQ10 synthesis.7 Rotig et al7 reported very low concentrations of labeled decaprenyl-diphosphate in patients' fibroblast extracts, consistent with a deficiency of trans-prenyltransferase; however, no mutations in the gene encoding trans-prenyltransferase were identified, suggesting that another gene involved in this pathway may be affected. Recently, mutations in the trans-prenyltransferase gene have been identified in 2 siblings with mild intellectual retardation, profound deafness, optic atrophy, valvulopathy, and obesity who had CoQ10 deficiency in fibroblasts but not in skeletal muscle.21

At least 4 different clinical manifestations of CoQ10 deficiency have been described: the encephalomyopathic form with myoglobinuria, ataxia, and seizures14-2; a predominantly cerebellar disease with ataxia and cerebellar atrophy5;18; a widespread multisystem involvement with hypertrophic cardiomyopathy, ataxia, optic nerve atrophy, deafness, generalized amyotrophy, and nephrotic syndrome4; and Leigh encephalopathy with growth retardation, ataxia, deafness, and lactic acidosis.6 The clinical heterogeneity found among patients with CoQ10 deficiency suggests that a number of biochemical and molecular defects may be involved in causing different clinical phenotypes.

The isolated myopathy with absence of central nervous system involvement and recurrent myoglobinuria

in our patient expands the clinical phenotype of CoQ10 deficiency. The complete recovery of myopathy with exogenous CoQ10 supplementation observed in this patient highlights the importance of early identification and treatment of this genetic disorder, perhaps offering a similar prognosis to patients affected with the myopathic form of this condition. Functional studies to identify the possible defect of ubiquinone synthesis in our patient are currently underway. This case demonstrates the need for detailed biochemical assessment of mitochondrial function in the diagnostic evaluation of isolated myopathies.
