**IMPORTANCE** Individuals in the presymptomatic stage of Alzheimer disease (AD) are increasingly being targeted for AD secondary prevention trials. How early during the normal life span underlying AD pathologies begin to develop, their patterns of change over time, and their relationship with future cognitive decline remain to be determined.

**OBJECTIVE** To characterize the within-person trajectories of cerebrospinal fluid (CSF) biomarkers of AD over time and their association with changes in brain amyloid deposition and cognitive decline in cognitively normal middle-aged individuals.

**DESIGN, SETTING, AND PARTICIPANTS** As part of a cohort study, cognitively normal (Clinical Dementia Rating [CDR] of 0) middle-aged research volunteers (n = 169) enrolled in the Adult Children Study at Washington University, St Louis, Missouri, had undergone serial CSF collection and longitudinal clinical assessment (mean, 6 years; range, 0.91-11.3 years) at 3-year intervals at the time of analysis, between January 2003 and November 2013. A subset (n = 74) had also undergone longitudinal amyloid positron emission tomographic imaging with Pittsburgh compound B (PiB) in the same period. Serial CSF samples were analyzed for β-amyloid 40 (Aβ40), Aβ42, total tau, tau phosphorylated at threonine 181 (P-tau181), visinin-like protein 1 (VILIP-1), and chitinase-3-like protein 1 (YKL-40). Within-person measures were plotted according to age and AD risk defined by APOE genotype (ε4 carriers vs noncarriers). Linear mixed models were used to compare estimated biomarker slopes among middle-age bins at baseline (early, 45-54 years; mid, 55-64 years; late, 65-74 years) and between risk groups. Within-person changes in CSF biomarkers were also compared with changes in cortical PiB binding and progression to a CDR higher than 0 at follow-up.

**MAIN OUTCOMES AND MEASURES** Changes in Aβ40, Aβ42, total tau, P-tau181, VILIP-1, and YKL-40 and, in a subset of participants, changes in cortical PiB binding.

**RESULTS** While there were no consistent longitudinal patterns in Aβ40 (P = .001-.97), longitudinal reductions in Aβ42 were observed in some individuals as early as early middle age (P ≤ .05) and low Aβ42 levels were associated with the development of cortical PiB-positive amyloid plaques (area under receiver operating characteristic curve = 0.9352; 95% CI, 0.8895-0.9808), especially in mid middle age (P < .001). Markers of neuronal injury (total tau, P-tau181, and VILIP-1) dramatically increased in some individuals in mid and late middle age (P = .02), whereas the neuroinflammation marker YKL-40 increased consistently throughout middle age (P ≤ .003). These patterns were more apparent in at-risk ε4 carriers (Aβ42 in an allele dose-dependent manner) and appeared to be associated with future cognitive deficits as determined by CDR.

**CONCLUSIONS AND RELEVANCE** Longitudinal CSF biomarker patterns consistent with AD are first detectable during early middle age and are associated with later amyloid positivity and cognitive decline. Such measures may be useful for targeting middle-aged, asymptomatic individuals for therapeutic trials designed to prevent cognitive decline.

Alzheimer disease (AD) is the most common cause of dementia in elderly individuals, accounting for up to 70% of all dementia cases, and is now estimated to be the third-leading cause of death after heart disease and cancer. To date, clinical trials of potential disease-modifying therapies for AD have met with little success in halting or slowing cognitive decline in patients who already have cognitive symptoms or dementia. However, clinicopathologic and more recent biomarker data suggest that AD pathology begins to accrue approximately 10 to 20 years before any cognitive signs or symptoms (termed asymptomatic or preclinical AD). Thus providing a window of opportunity for the initiation of secondary prevention trials that aim to prevent the development of symptoms in individuals while they are still cognitively normal. How early during the normal life span such pathologies begin to develop, their patterns of change over time, and their relationship with future cognitive decline remain to be determined.

Because, by definition, preclinical AD eludes detection by current clinical measures, disease-specific biomarkers are necessary to identify individuals in this asymptomatic stage. To this end, the Adult Children Study (ACS) of the Knight Alzheimer’s Research Center at Washington University, St. Louis, Missouri, was initiated. The ACS is a longitudinal clinical and biomarker research study of cognitively normal, middle-aged adults exhibiting different AD risk profiles including age, family history of AD, and APOE genotype (APOE ε4 carriers vs noncarriers). Participants undergo comprehensive, longitudinal clinical and psychometric assessments and evaluation of biomarkers in cerebrospinal fluid (CSF) and plasma, along with several imaging modalities. We hypothesized that biomarker patterns indicative of underlying AD pathology would be evident in a subset of cognitively normal individuals during middle age, at a greater frequency than those at higher risk for AD (ie, older and/or carrying the ε4 allele of APOE), and would increase in severity over time, ultimately culminating in cognitive decline.

The 3 CSF biomarker analytes that reflect the core neuro-pathologies in AD, β-amyloid 42 (Aβ42; the primary constituent of amyloid plaques), total tau (a marker of neuronal injury and/or death), and hyperphosphorylated tau (P-tau; forms intraneuronal neurofibrillary tangles), demonstrate excellent diagnostic and prognostic utility in research cohorts. Other recently identified biomarkers, including visinin-like protein 1 (VILIP-1) and chitinase-3-like protein 1 (YKL-40) (markers of neuronal death and gliosis/neuroinflammation, respectively) have also demonstrated clinical utility in AD, especially when combined in an algorithm with CSF Aβ42. This first report of longitudinal biomarker changes in the ACS cohort describes the within-person trajectories of these CSF biomarkers over time and their association with longitudinal changes in in vivo amyloid imaging and future cognitive decline as a function of risk conferred by APOE genotype.

Methods

Participants

Participants were cognitively normal, community-dwelling research volunteers enrolled in the ACS at the Knight Alzheimer’s Disease Research Center at Washington University. Inclusion criteria include the following: (1) positive family history (≥1 biological parent with age at AD dementia onset <80 years) or negative family history (both biological parents living to age ≥70 years in the absence of AD dementia); (2) aged 45 to 74 years at study entry (1 enrollee was aged 43 years, 3 were aged 75 years, 3 were aged 76 years, and 1 was aged 81 years); (3) availability of an informant who knows the participant well; (4) normal cognition at study entry (defined as having a Clinical Dementia Rating [CDR] of 0); and (5) willingness in principle to complete all study procedures at baseline and longitudinally. Exclusion criteria include the following: (1) presence of a neurological, psychiatric, or systemic illness that might affect cognition or interfere with longitudinal follow-up; (2) a known deterministic mutation for AD; and (3) medical contra-indication to lumbar puncture for CSF collection or imaging.

Clinical and Cognitive Assessments

The presence or absence of dementia (and, when present, its severity) was operationalized with the CDR in accordance with standard protocols and criteria. A CDR of 0 indicates cognitive normality, whereas CDRs of 0.5, 1, 2, and 3 are indicative of very mild, mild, moderate, and severe dementia, respectively.

Genotyping

Using standard procedures, DNA was extracted from peripheral blood samples. Genotyping of APOE was performed by the Knight Alzheimer’s Disease Research Center Genetics Core as previously described.

CSF Collection and Processing

A sample of CSF (20-30 mL) was collected by routine lumbar puncture at 8 AM after overnight fasting as described. Samples were processed into 500-μL aliquots and immediately frozen at –80°C.

CSF Biomarker Analyses

The eTable in the Supplement shows the details of the kit specifications and general assay performance. The CSF samples were analyzed for Aβ and tau proteins using single-analyte enzyme-linked immunosorbent assays (ELISAs; research use only) from 2 different vendors. Samples were analyzed for Aβ1-40 (Aβ40), Aβ1-42 (Aβ42), total tau, and tau phosphorylated at threonine 181 (P-tau181) using the Improved INNOTEST ELISA (Fujirebio Europe), a modified version of the assay most widely used in the field. In parallel, Aβ40, Aβ42, and total tau were measured at the same time (from the same sample aliquot) using a set of second-generation (precision-based and accuracy-
Based) EUROWIMMUN ELISAs (EUROWIMMUN). The Aβ42 to Aβ40 ratio was calculated to normalize the Aβ42 production concentrations to the total amount of Aβ (Aβ40 is the most abundant Aβ species in CSF).15-22 The ratio of total tau (or P-tau181) to Aβ42 was also evaluated because it has been shown to be a predictor of future cognitive decline in elderly cohorts.17,28-30 It must be stated at the outset that the focus of this study is on the clinical utility of the biomarker and that conclusions drawn from one assay can be confirmed or qualified with data derived from another immunoassay. The well-studied INNOTEST ELISA was considered a priori to be the reference assay; therefore, INNOTEST data are shown.

The VILIP-1 concentration was measured using a 2-site immunoassay (Singulex).13 The YKL-40 concentration was measured using the MicroVue ELISA (Quidel).16 Longitudinal CSF samples from a given individual were run on the same assay plate (and same lot number) to minimize potential interplate and interlot methodological variability. Samples underwent a single freeze-thaw cycle prior to assay, were thawed on wet ice (approximately 3 hours) prior to analysis, and were all run in duplicate. Values had to pass quality control criteria, including coefficients of variation of 25% or lower, kit controls within the expected range as defined by the manufacturer (where applicable), and measurement consistency of 2 common pooled CSF samples that were included on each plate.

In Vivo Amyloid Imaging
A subset (n = 74) of the 169 participants with longitudinal analysis had also undergone longitudinal in vivo amyloid CSF imaging via positron emission tomography (PET) with Pittsburgh compound B (PiB)31-33 within approximately 12 months of CSF collection (mean [SD], 84.3 [92] days). The PiB PET imaging was conducted with a Siemens 962 HR+ Emission Computer-Aided Tomograph PET or Biograph 40 scanner (Siemens/CTI). Magnetic resonance imaging using magnetization-prepared rapid-acquisition gradient-echo T1-weighted images (1 × 1 × 1.25 mm) was obtained for anatomical reference. Deposition of PiB in brain regions of interest was determined using FreeSurfer version 5.1 software (Martinos Center for Biomedical Imaging),34,35 and a standardized uptake value ratio (SUVR) corrected for partial volume effects36 was calculated for each region of interest. The mean cortical SUVR was calculated from FreeSurfer regions within the prefrontal cortex, precuneus, and temporal cortex. Cerebellar cortex served as the reference region. Based on a study of 77 symptomatic and asymptomatic Knight Alzheimer’s Disease Research Center participants,32 PiB positivity was defined as an SUVR of 1.42, commensurate with a mean cortical binding potential of 0.18 defined previously for PiB positivity.31

Statistical Analysis
Baseline demographic characteristics were summarized as mean (standard deviation) for continuous variables or number (percentage) for categorical variables. Demographic variables were compared across 3 age bins within the 2 APOE ε4 groups and between the ε4 carriers and noncarriers within each age bin using post hoc t tests within analysis of variance for continuous variables or logistic regression for dichotomous variables. To quantify the within-person annual rate of change in CSF biomarkers, general linear mixed models with random intercepts and random time slopes at the participant level were used to regress the concentrations on time from study entry (baseline). These models incorporated baseline age category, APOE category, and time from study entry as fixed effects as well as all possible higher-order interactions among these factors. This facilitated the estimation of average baseline CSF biomarker concentrations as well as their change over time separately in each of the 6 participant groups (cross-classification of 3 baseline age categories by 2 APOE categories). The resulting estimated average within-person annual rates of change in CSF biomarkers were compared among the 6 groups with model-derived approximate t tests with the approximate denominator df based on the Satterthwaite approximation.37 Baseline comparisons between CSF biomarkers among the groups in Table 1 were also carried out within these general linear mixed models by testing the estimated average concentrations when time from study entry was equal to 0. These CSF biomarker comparisons, at baseline and on the longitudinal rate of change, were also reexamined after adjusting for family history, sex, and education by including fixed effects for these factors and their interactions with time from study entry. The general linear mixed models assumptions were evaluated via analyses of residuals. Owing to the preliminary nature of hypotheses examined in this cohort, no adjustment was made for multiplicity. For exploratory purposes, an optimal CSF Aβ42 cutoff was determined using the Youden Index after receiver operating characteristic analysis for discriminating between PiB-positive and PiB-negative individuals at baseline. For each biomarker, baseline and longitudinal comparisons between PiB-positive (PiB SUVR ≥ 1.42) and PiB-negative individuals were performed using linear mixed models with fixed effects included for PiB category, time from study entry, and their interaction. We used SAS version 9.3 statistical software (SAS Institute, Inc) for all statistical analyses, with statistical significance defined as P < .05.

Results
Baseline data are presented in Table 1 and grouped into 6 bins: the absence (n = 108) or presence (n = 61) of at least 1 APOE ε4 allele (as an indicator of neutral and high AD risk, respectively) and middle-age bin at baseline (early [45-54 years], mid [55-64 years], or late [65-74 years]). Ninety-nine participants underwent 2 serial CSF collections, 65 underwent 3 serial CSF collections, and 5 underwent 4 serial CSF collections, at intervals of approximately 3 years. Forty-five of the 61 ε4 carriers (74%) and 49 of the 108 ε4 noncarriers (45%) reported a positive family history.

Comparison of the CSF Aβ40, Aβ42, and Total Tau Assays
Concentrations of Aβ40, Aβ42, and total tau obtained with the 2 assays were positively correlated (Aβ40, n = 412, Pearson r = 0.772 [95% CI, 0.730-0.808], P < .001; Aβ42, n = 394, Pearson r = 0.879 [95% CI, 0.855-0.900], P < .001; total tau, n = 410,

*Significantly different from mid within the same APOE ε4 group (P < .05).

Significantly different from the same age group of the other APOE ε4 group (P < .05).

The MMSE scores can range from 0 to 30, with 30 as a perfect score.

A CDR of 0 indicates cognitively normal; a CDR higher than 0, cognitively abnormal.

Significantly different from early within the same APOE ε4 group (P < .05).
mid (noncarriers, levels in ε4 carriers were significantly lower in the participants as early as 45 to 54 years of age. While baseline (Figure 1BandTable2), and this pattern was detectable in many in all age groups were observed for Aβ42 in both risk groups, with intermediate levels in the mid middle-aged participants, although differences were statistically significant only in the ε4 noncarriers (P < .001 and P = .02, respectively) (Table 1). Within ε4 noncarriers, total tau increased significantly over time during late middle age (P < .001), while increases were observed earlier (mid and late middle age) in the higher-risk ε4 carriers (both P < .001) (Figure 1D and Table 2). Interestingly, the annual mean (SE) increase in total tau in mid middle age was significantly higher in ε4 carriers (22.28 [4.45] pg/mL) compared with ε4 noncarriers (2.84 [2.68] pg/mL) (P < .001) (Table 2). Results for P-tau181 were virtually identical to those for total tau, including more robust elevations in the ε4 carriers during mid middle age (Figure 1E and Table 2).

**Baseline and Slope Analyses: CSF Biomarker Changes Occur in Middle Age**

Baseline biomarker levels (Table 1) and slopes of change within individuals (Table 2) were evaluated in the 6 bins defined earlier. Slopes were calculated as the representative mean of all annual individual slopes per age bin (extrapolated to 9 years for illustrative purposes) and superimposed on the spaghetti plots of the associated individual trajectories (Figure 1 shows the INNOTEST assay data for Aβ40, Aβ42, Aβ42 to Aβ40 ratio, total tau, P-tau181, and total tau to Aβ42 ratio; Figure 2 shows the data for VILIP-1 and YKL-40; eFigure 1 in the Supplement shows the EUROIMMUN assay data). Controlling for family history, sex, and education did not substantially influence the comparisons between age and ε4 categories.

**Aβ40, Aβ42, and Aβ42 to Aβ40 Ratio**

Baseline levels of CSF Aβ40 (INNOTEST) were significantly higher in the late middle-aged group compared with the early middle-aged group in ε4 noncarriers (P = .004) (Table 1) but decreased significantly within individuals in the early (P = .04) and mid (P = .01) middle-aged groups over time (Table 2 and Figure 1A). In contrast, no significant differences were observed in ε4 carriers at baseline or longitudinally (Table 1 and Table 2).

In contrast to Aβ40, robust decreases within individuals in all age groups were observed for Aβ42 in both risk groups (Figure 1B and Table 2), and this pattern was detectable in many participants as early as 45 to 54 years of age. While baseline concentrations did not differ among the age groups in the ε4 noncarriers, levels in ε4 carriers were significantly lower in the mid (P < .001) and late (P < .001) middle-aged groups compared with the early middle-aged group and also significantly lower than the levels in the mid (P < .001) and late (P < .001) middle-aged ε4 noncarriers (Table 1).

Similar to the patterns observed for Aβ42 alone, the ratios of Aβ42 to Aβ40 were significantly lower in the mid (P = .02) and late (P = .005) middle-aged groups compared with the early middle-aged group in ε4 carriers (Table 1), and the within-person values significantly decreased over time in the 2 older age groups (both P < .001) (Figure 1C and Table 2). Although baseline ratios in the ε4 noncarriers were significantly lower in the late middle-aged group compared with the mid (P = .05) and early (P = .004) middle-aged groups (Table 1), they did not change significantly within these low-risk individuals at any age (Figure 1C and Table 2).

**Total Tau and P-tau**

Baseline total tau was higher in late middle-aged participants compared with early middle-aged participants in both risk groups, with intermediate levels in the mid middle-aged participants, although differences were statistically significant only in the ε4 noncarriers (P < .001 and P = .02, respectively) (Table 1). Within ε4 noncarriers, total tau increased significantly over time during late middle age (P < .001), while increases were observed earlier (mid and late middle age) in the higher-risk ε4 carriers (both P < .001) (Figure 1D and Table 2). Interestingly, the annual mean (SE) increase in total tau in mid middle age was significantly higher in ε4 carriers (22.28 [4.45] pg/mL) compared with ε4 noncarriers (2.84 [2.68] pg/mL) (P < .001) (Table 2). Results for P-tau181 were virtually identical to those for total tau, including more robust elevations in the ε4 carriers during mid middle age (Figure 1E and Table 2).

**Aβ42, Aβ40, and Aβ40 to Aβ42 Ratio**

Baseline levels of CSF Aβ40 (INNOTEST) were significantly higher in the late middle-aged group compared with the early middle-aged group in ε4 noncarriers (P = .004) (Table 1) but decreased significantly within individuals in the early (P = .04) and mid (P = .01) middle-aged groups over time (Table 2 and Figure 1A). In contrast, no significant differences were observed in ε4 carriers at baseline or longitudinally (Table 1 and Table 2).

In contrast to Aβ40, robust decreases within individuals in all age groups were observed for Aβ42 in both risk groups (Figure 1B and Table 2), and this pattern was detectable in many participants as early as 45 to 54 years of age. While baseline concentrations did not differ among the age groups in the ε4 noncarriers, levels in ε4 carriers were significantly lower in the mid (P < .001) and late (P < .001) middle-aged groups compared with the early middle-aged group and also significantly lower than the levels in the mid (P < .001) and late (P < .001) middle-aged ε4 noncarriers (Table 1).

Similar to the patterns observed for Aβ42 alone, the ratios of Aβ42 to Aβ40 were significantly lower in the mid (P = .02) and late (P = .005) middle-aged groups compared with the early middle-aged group in ε4 carriers (Table 1), and the within-person values significantly decreased over time in the 2 older age groups (both P < .001) (Figure 1C and Table 2). Although baseline ratios in the ε4 noncarriers were significantly lower in the late middle-aged group compared with the mid (P = .05) and early (P = .004) middle-aged groups (Table 1), they did not change significantly within these low-risk individuals at any age (Figure 1C and Table 2).

**Total Tau and P-tau**

Baseline total tau was higher in late middle-aged participants compared with early middle-aged participants in both risk groups, with intermediate levels in the mid middle-aged participants, although differences were statistically significant only in the ε4 noncarriers (P < .001 and P = .02, respectively) (Table 1). Within ε4 noncarriers, total tau increased significantly over time during late middle age (P < .001), while increases were observed earlier (mid and late middle age) in the higher-risk ε4 carriers (both P < .001) (Figure 1D and Table 2). Interestingly, the annual mean (SE) increase in total tau in mid middle age was significantly higher in ε4 carriers (22.28 [4.45] pg/mL) compared with ε4 noncarriers (2.84 [2.68] pg/mL) (P < .001) (Table 2). Results for P-tau181 were virtually identical to those for total tau, including more robust elevations in the ε4 carriers during mid middle age (Figure 1E and Table 2).

**Ratios of Total Tau and P-tau**

In ε4 noncarriers, the baseline total tau to Aβ42 ratio was significantly higher in late middle age compared with both early (P = .005) and mid (P = .01) middle age (Table 1). In at-risk ε4 carriers, significantly higher ratios were observed even earlier (mid [P = .002] and late [P = .004] middle age) compared with early middle age (Table 1). Longitudinal patterns for the total tau to Aβ42 ratio were virtually identical to those of total tau, with significant within-person increases in the late middle-aged group in ε4 noncarriers (P < .001) and even earlier (mid and late middle age) in the ε4 carriers (both P < .001) (Figure 1F and Table 2). Patterns for the P-tau181 to Aβ42 ratio were virtually identical to those of the total tau to Aβ42 ratio (data not shown).

**Other Biomarkers of Neuronal Injury and Gliosis/Neuroinflammation**

**VILIP-1 Concentration**

The concentration of VILIP-1 was positively correlated with total tau during middle age (INNOTEST total tau: n = 401, Pearson r = 0.763 [95% CI, 0.719-0.801], P < .001; EUROIMMUN total tau: n = 403, Pearson r = 0.743 [95% CI, 0.696-0.784], P < .001), consistent with earlier reports in elderly cohorts. Similar to total tau, mean baseline VILIP-1 concentration increased with age, with significantly higher levels in late middle age compared with early (P = .008) and mid (P = .03) middle age in the ε4 noncarriers (Table 1) and within-person increases over time in late middle age (P = .02) (Figure 2A and Table 2). While baseline levels of VILIP-1 in the at-risk ε4 carriers at baseline were not significantly different among the age groups (Table 1), they significantly increased longitudinally within individuals at an earlier age (mid middle age [P < .001]) compared with the ε4 noncarriers (late middle age [P < .02]) (Figure 2A and Table 2). Also similar to total tau, the annual mean increase in VILIP-1 concentration in mid middle age was greater in ε4 carriers compared with ε4 noncarriers (P < .001).
YKL-40 Concentration | Baseline CSF YKL-40 concentration was significantly higher in mid and late middle age compared with early middle age in both ε4 groups (all $P ≤.04$) as well as in late middle age compared with mid middle age in the ε4 noncarriers ($P < .001$) (Table 1). In both groups, YKL-40 concentration significantly increased within indi-
Figure 1. Longitudinal Change in Cerebrospinal Fluid Biomarkers β-Amyloid 40 (Aβ40), Aβ42, Aβ42 to Aβ40 Ratio, Total Tau, Tau Phosphorylated at Threonine 181 (P-tau181), and Total Tau to Aβ42 Ratio During Middle Age

Estimated group slopes and within-person changes for Aβ40 (A), Aβ42 (B), Aβ42 to Aβ40 ratio (C), total tau (D), tau phosphorylated at threonine 181 (P-tau181) (E), and total tau to Aβ42 ratio (F) are shown in the 3 age bins for APOE ε4 noncarriers (top graph of each panel; n = 108 participants) and ε4 carriers (bottom graph of each panel; n = 61 participants). Annual slopes have been extrapolated to 9 years, and each slope begins at the mean baseline biomarker value from individuals in each age bin. Group baseline values and slopes represent the estimates reported in Table 1 and Table 2, respectively, for the different cohorts defined by baseline age in which biomarker concentrations were regressed on time from study entry. Data are from the INNOTEST enzyme-linked immunosorbent assay (Fujirebio Europe).

* Slope significantly different from 0 (P < .05).

individually over time in all age bins (P = .002 in late middle age among ε4 noncarriers; all others, P < .001) (Figure 2B and Table 2). In mid middle age, YKL-40 concentration increased at a significantly higher rate in the ε4 carriers compared with ε4 noncarriers (P = .001) (Table 2), similar to what was observed for the injury markers.

**APOE ε4 Gene Dose Influences CSF Biomarker Patterns Consistent With the Presence of Preclinical AD During Middle Age**

Given the known APOE ε4 gene dosage effects on the risk of AD and age at dementia onset, we evaluated biomarker trajectories as a function of ε4 allele number. The majority (82%) of ε4 noncarriers had the ε3/ε3 genotype, whereas the majority (75%) of ε4 carriers had the ε3/ε4 genotype (Table 1). Nine participants were ε4 homozygotes (ε4/ε4 genotype). Trajectory patterns for Aβ40 did not differ as a function of ε4 allele dose (eFigure 2A in the Supplement). In contrast, patterns differed dramatically for Aβ42 (eFigure 2B in the Supplement) and the Aβ42 to Aβ40 ratio (data not shown) across the entire age range, with ε4 homozygotes falling among the lowest values, ε4 noncarriers typically falling among the highest, and heterozygotes falling in the middle range (although overlapping with many of the ε4 noncarriers). The longitudinal patterns for total tau, total tau to Aβ42 ratio, VILIP-1, and YKL-40 in ε4 carriers appeared to overlap to a greater extent with those for ε4 noncarriers (eFigure 2C-F in the Supplement). However, the number of ε4 homozygotes is too small to perform rigorous statistical analyses in the current cohort.

**Association of CSF Aβ42 and In Vivo Amyloid Imaging During Middle Age**

Because studies to date evaluating the concordance of CSF Aβ42 concentrations with in vivo amyloid load have focused on elderly cohorts, it was of interest to characterize this association in middle age, a time during which a subset of individuals are expected to be in the very earliest stages of preclinical AD. This analysis used data from a subset of 74 participants (n = 50 ε4 noncarriers; n = 24 ε4 carriers) within the longitudinal CSF cohort who had also undergone longitudinal in vivo PiB PET imaging within 376 days (mean [SD], 84.3 [92] days) of CSF collection. Twenty of these individuals were considered PiB positive (mean cortical SUVR ≥ 1.42) at baseline, follow-up, or both (Figure 3A). Of these 20 individuals, 10 (50%) were ε4 noncarriers and 10 (50%) were ε4 carriers. Although there was no significant association between the cross-sectional patterns (P = .12) or longitudinal trajectories (P = .65) of Aβ40 and cortical PiB binding (Figure 3B), PiB positivity was associated with low baseline levels of CSF Aβ42 (P < .001) but not longitudinal change (P = .37) (Figure 3C). However, 15 PiB-negative individuals (20%) had concentrations of Aβ42 that were as low as those who were PiB positive. Because low Aβ42 values could conceivably reflect low production of all Aβ species rather than an amyloidosis-specific decrease in Aβ42, we also evaluated the relationship between PiB and the Aβ42 to Aβ40 ratio (Figure 3D). Twelve of the PiB-negative participants (16%) had Aβ42 to Aβ40 ratios at some point that were as low as those who were PiB positive. Notably, all 4 ε4 homozygotes in this subcohort had a low Aβ42 concentration and a low Aβ42 to Aβ40 ratio at both baseline and follow-up (Figure 3C and D), including the 2 young participants (aged 55 years at baseline) who were PiB negative (Figure 3C and D, solid black lines). The PiB-positive individuals typically had higher baseline (P < .001) and longitudinally increasing (P < .001) levels of total tau (and P-tau181 [scatterplots not shown]) compared with those who were PiB negative (Figure 3E). The PiB associations with baseline (P = .04) and longitudinal (P = .004) VILIP-1 concentrations were similar to total tau but less concordant (Figure 4A). Being PiB positive was not significantly asso-
A subset (n = 74) of Adult Children Study participants had undergone longitudinal amyloid imaging via PiB positron emission tomographic imaging within 376 days (mean [SD], 84.3 [92] days) of cerebrospinal fluid collection. Biomarker measures include cortical PiB SUVR (A), Aβ40 (B), Aβ42 (C), Aβ42 to Aβ40 ratio (D), and total tau (E). The Aβ40, Aβ42, and total tau were analyzed by INNOTEST enzyme-linked immunosorbent assay (Fujirebio Europe). Being PiB positive was defined as having a mean cortical PiB SUVR higher than 1.42 and is represented by the dashed horizontal line in panel A. Gray lines indicate PiB negative at baseline and follow-up (n = 52); solid colored lines, PiB positive at both baseline and follow-up (n = 14); dashed colored lines, PiB negative at baseline but positive at follow-up (n = 6); and solid black lines, PiB negative with discordant (low) cerebrospinal fluid Aβ measures at baseline and follow-up (n = 2). Colored solid and dashed lines are each differently colored only to facilitate visual comparisons across all analytes for each PiB-positive individual.

Aβ42 Cutoff as Estimated Using PiB at Baseline
Using only baseline CSF and PiB obtained within 376 days (mean [SD], 89.9 [95] days), a slightly larger subcohort of 105 participants was used to calculate a cutoff for CSF Aβ42 (INNOTEST) based on PiB positivity. The optimal cutoff in this
cohort is 1041 pg/mL (sensitivity = 1; specificity = 0.82), with an area under the receiver operating characteristic curve of 0.9352 (95% CI, 0.8895-0.9808).

Case Study of Participants Who Received a CDR Higher Than 0 at Clinical Follow-up

Biomarker studies in cognitively normal elderly cohorts have demonstrated prognostic utility of baseline CSF measures for predicting future cognitive decline. To assess whether this relationship exists even earlier in the preclinical stages (during middle age), as a preliminary analysis we compared the biomarker trajectories in participants who received a CDR higher than 0 at some point during clinical follow-up with those who retained a CDR of 0. Of the 169 participants evaluated, all of whom were cognitively normal (CDR of 0) at the time of baseline CSF collection, 14 received a CDR of 0.5 at some point during follow-up (mean [SD], 6.55 [1.94] years; median, 6.15 years; range, 4.21-10.28 years), and 3 of these progressed further to a CDR of 1. The remaining 155 participants had a CDR of 0 at all follow-up (mean [SD], 6.01 [1.94] years; median, 6.21 years; range, 0.98-11.32 years). The duration of follow-up did not differ significantly between the groups (P > .05). All individuals who progressed to a CDR higher than 0 were older than 61 years at baseline. There was no apparent relationship between baseline or longitudinal trajectories of Aβ40 and cortical amyloid (Figure 5A). In contrast, the majority of progressors exhibited low Aβ42 (Figure 5B) and Aβ42 to Aβ40 ratio (data not shown) at baseline and follow-up and high total tau and total tau to Aβ42 ratio (Figure 5C and D). Patterns of VILIP-1 and YKL-40 did not appear to differ between the clinical groups (Figure 5E and F). However, the number of clinical progressors is too small to perform rigorous statistical analyses in the current cohort.

Discussion

Our results demonstrate the following: (1) levels of CSF Aβ42 in some cognitively normal individuals decrease over time, starting as young as early middle age (45-54 years); (2) in mid middle age (55-64 years), reductions in Aβ42 are associated with the development of PIB-positive amyloid plaques; (3) elevations in neuronal injury markers total tau, P-tau181, and (to a lesser extent) VILIP-1 increase dramatically in some individuals throughout middle age suggest an ongoing pathologic process that for some people starts quite early (ages 45-54 years). Levels may begin to decrease even earlier, but additional investigation in younger cohorts is needed to test this hypothesis. During middle age, the timing of this decrease is influenced by ε4 allele dosage, consistent with studies demonstrating a major influence of APOE genotype on Aβ aggregation and clearance. Baseline and follow-up Aβ42 levels are among the lowest in ε4 homozygotes compared with heterozygotes and ε4 noncarriers, with reductions evident at earlier ages. Such effects are consistent with the ε4 dosage effects on age at dementia onset.
Regardless of when Aβ42 levels begin to decrease during the preclinical period, these decreases did not coincide with the presence of amyloid detectable by PiB PET until mid-middle age. The Aβ42 level was stably low or beginning to decline in some individuals while cortical PiB binding was still below the threshold of positivity, and PiB binding did not begin to increase until the CSF Aβ42 level was already relatively low. Thus, it seems likely that Aβ42 aggregation can be detected earlier with CSF analysis than with cortical PiB PET imaging, consistent with recent studies in autosomal dominant AD. This is highlighted by 2 high-risk early-middle-aged ε4 homozygotes who had stable, low Aβ42 levels (and Aβ42 to Aβ40 ratios) in longitudinal samples but were PiB negative. This observation may reflect sequestra-

Figure 5. Cerebrospinal Fluid Biomarker Trajectories in Participants Receiving a Clinical Dementia Rating Higher Than 0 at Some Point During Clinical Follow-up

Within-person trajectories of cerebrospinal fluid β-amyloid 40 (Aβ40) (A), Aβ42 (B), total tau (C), total tau to Aβ42 ratio (D), visinin-like protein 1 (VILIP-1) (E), and chitinase-3-like protein 1 (YKL-40) (F) are plotted as a function of age. The Aβ40, Aβ42, and total tau were analyzed by INNOTEST enzyme-linked immunosorbent assay (Fujirebio Europe). Fourteen individuals received a Clinical Dementia Rating of 0.5 or 1 at some point during follow-up (mean [SD], 6.55 [1.94] years; range, 4.21-10.28 years). Orange lines indicate individuals who received a Clinical Dementia Rating higher than 0 at available follow-up visits; gray lines, individuals who did not receive a Clinical Dementia Rating higher than 0.
tion of Aβ42 into oligomeric forms undetectable with the current assays or its deposition in nonfibrillar (PiB-negative) diffuse plaques. In support of the latter, low CSF Aβ42 concentration in the absence of PiB positivity has been reported in a case in which numerous diffuse plaques, but few neuritic plaques, were observed at autopsy.42 However, the early middle-age bin of the longitudinal PiB subcohort is quite small; subregional PiB analyses and evaluation of future longitudinal PiB scans in ACS participants are necessary to rigorously evaluate PiB changes in early middle age.

The calculated CSF Aβ42 cutoff in this cohort is quite high at 1041 pg/mL, higher than previously reported using the INNOTEST kit (typically 450–650 pg/mL).43,44 This apparent discrepancy may reflect the younger age of the ACS cohort. Most likely it reflects the fact that we used a newer modified, improved INNOTEST assay. This cutoff is not suggested for clinical use but was instead provided to evaluate amyloid positivity using CSF measures—similar to protocols suggested for clinical use but was instead provided to evaluate amyloid positivity using CSF measures—similar to protocols used in the ACS cohort for enrollment in AD prevention trials. Using this cutoff, 51 of the 169 participants (30%) would be considered amyloid positive and eligible for clinical trials. This cohort enrolls participants with and without family history of AD for longitudinal imaging and CSF biomarker studies; participants may not be representative of the general population. Despite the large number of participants in this unique cohort, there are fewer in the ε4-carrying group, and most participants at the time of analysis had only 2 longitudinal samples available. While some individuals had 10 years of clinical follow-up, others had only 4. Although the results provide support for a scenario in which changes in amyloid-related processes precede those of tau or other neurodegeneration-related processes, additional analyses during a longer period are required to determine the precise sequence of biomarker changes within a given individual. Furthermore, as expected in such a young, asymptomatic cohort, relatively few participants in this initial report had received a CDR greater than 0 during follow-up. Continued evaluation of longer clinical follow-up will provide an opportunity to better elucidate the biomarker patterns in middle age that predict future cognitive decline.

**Conclusions**

The present groupwide analyses are supportive of a preclinical period of AD in which biomarker patterns consistent with underlying disease pathology are first detectable during middle age, the timing of which is influenced by APOE genotype, with amyloid changes occurring prior to neuronal injury. However, proposals to use biomarkers in clinical settings require demonstration of their utility on a patient-by-patient basis. Importantly, our preliminary findings of an association between CSF biomarker positivity in specific individuals who go on to develop cognitive deficits within a few years provide support for such potential use.

Author Contributions: Ms Sutphen and Mr Jasielec had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study concept and design: Sutphen, Holtzman, Fagan.

Acquisition, analysis, or interpretation of data: Sutphen, Jasielec, Shah, Macy, Xiong, Vlassenko, Benzinger, Stoops, Vanderstichele, Brix, Darby, Vandijck, Ladenson, Morris, Fagan.

Drafting of the manuscript: Sutphen, Fagan.

Critical revision of the manuscript for important intellectual content: All authors.

Statistical analysis: Jasielec, Xiong. Obtained funding: Benzinger, Morris, Holtzman. Administrative, technical, or material support: Shah, Stoops, Vanderstichele, Brix, Darby, Vandijck, Ladenson.

Study supervision: Xiong, Fagan.

Conflict of Interest Disclosures: Dr Benzinger reported being a member of the advisory board for Eli Lilly and Co (2011); receiving research funding from Avid Radio pharmaceuticals; providing expert testimony and receiving compensation from Kujawski and Associates (2011); and participating in clinical trials sponsored by Eli Lilly and Co, Avid Radio pharmaceuticals, and Roche. Mr Stoops reported being a shareholder of ADX NeuroSciences and BiomarIC NV. Dr Vanderstichele reported being a co-founder and shareholder of ADX NeuroSciences and founder of Biomarkable bvba. Dr Ladenson reported being named on patents related to use of VILIP-1; these are being managed by Washington University in accordance with university policy. Dr Morris reported having participated in or currently participating in clinical trials of antiedementia drugs sponsored by Janssen Immunotherapy, Pfizer, Eli Lilly and Co/Avid Radio pharmaceuticals, SNIF (Study of Nasal Insulin to Fight Forgetfulness), and A4 Study (Anti-Amyloid Treatment in Asymptomatic Alzheimer’s Disease) and serving as a consultant for Lilly USA, ISIS Pharmaceuticals, and the Charles Dana Foundation. Dr Holtzman reported being a cofounder of C2N Diagnostics LLC; serving on the scientific advisory boards of AstraZeneca, Genentech, NeuroPhage, and C2N Diagnostics; and serving as a consultant for Eli Lilly and Co. Washington University receives grants to the laboratory of Dr Holtzman from the Tau Consortium, Cure Alzheimer’s Fund, the JPB Foundation, Eli Lilly and Co, Janssen, and C2N Diagnostics. Dr Fagan reported serving on the scientific advisory boards of IBL International and Roche and serving as a consultant for AbbVie and Novartis. No other disclosures were reported.

Funding/Support: This work was supported by grants PO1AG026276 (Dr Morris), SP30 NS048056 (Dr Benzinger), and SP30 NS048056 (Dr Benzinger) from the National Institutes of Health, the Barnes-Jewish Hospital Foundation (Dr Morris), the Fred Simmons and Olga Mohan fund (Dr Morris), and a grant from Eli Lilly and Co (Dr Holtzman).

Role of the Funder/Sponsor: The funders had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Additional Contributions: Genotyping of APOE was performed under the direction of Alison Goate, DPhil, Genetics Core, Knight Alzheimer’s Disease Research Center, Washington University, St Louis, Missouri; she received no compensation. Matthew Amos, Elizabeth Grant, PhD, and Sushila Sathyam, MA, Knight Alzheimer’s Disease Research Center, Washington University, provided technical support; they received no compensation. We acknowledge the contributions of the ACS Administration, Clinical Biomarker, Imaging, and Biostatistics Cores at the Knight Alzheimer’s Disease Research Center. We gratefully acknowledge the altruism of the ACS participants and their families.
